Insect Control

Field Investigation of Effect of Insect Damage Chang-
ing Composition in Lodgepole Pine - Flint & Gisborne

MEMORANDUM

On October 30 to November 1 inclusive, a field examination was made of some of the areas of insect killed lodgepole pine in the vicinity of Monture Ranger Station on the Missoula National Forest. The purpose of the work was to secure more detailed information concerning the following phases of the insect infestation:

1. Amount and character of the damage in typical stands of lodgepole pine.
2. Composition and character of the remaining stand.
3. Influence of the insect work on fire risk.
4. Probable future of this stand from a silvicultural standpoint.

It is known that the area of recently killed lodgepole pine in this part of Montana is very great, and that it is rather steadily increasing. During the past year, fresh work has been observed on the Helena Forest and in the South Fork of the Flathead in the vicinity of Big Prairie. Fresh work is also reported in the Fortine and Wolf Creek districts of the Blackfoot Forest. Knowing this to be true, it is evident that studies similar to this one should be made to provide a basis for the formulation of a policy to govern insect control work. There is very little exact information available on the subject at this time. Control measures, if undertaken, will be expensive and should be based on full and accurate information.

From the best information available, it seems probable that the infestation in the vicinity of Monture Station first became of epidemic proportions about 1914, and that it had practically ceased on these particular areas by 1918. The epidemic appears to travel in a more or less progressive fashion over the lodgepole areas. Active work in a given tract apparently ceases when the most suitable host trees have been killed. The insects appear to choose moving to a new

Copy filed RS-Pi

Memo.

locality in preference to working on trees less than about six inches in diameter breast high. This belief is borne out by observations on a recent control project involving the treatment of about 500 lodgepole trees on the Helena National Forest. Of the infested trees on the Helena 79 per cent were in the dominant and codominant classes, and practically no trees six inches or less in diameter breast high were infested regardless of the fact that the stand was a dense even aged one with many trees of small diameter. There is no evidence that the epidemic near Monture was checked by any agent or condition other than the exhaustion of the supply of suitable host trees.

In the vicinity of Monture Ranger Station, twenty or more chains of strip were run on each of three exposures; level bench at low altitude, (approximately 4100 feet above sea), steep northerly slope at approximately 5000 feet, and steep southerly slope at approximately 4500 to 5000 feet. All live and dead standing, or recently down, lodgepole and yellow pine trees, and all green trees of other species, 6 inches in diameter or larger, were tallied by two-inch diameter classes, using the quarter acre circular plot method. A six-inch diameter limit was chosen arbitrarily because it was apparent that but very few trees smaller than six inches D.B.H. had been attacked by insects. All live trees less than six inches D.B.H. and all reproduction and seedlings of all species were tallied by the mil-acre plot system, described by Lowdermilk in Applied Forestry Notes, August, 1917.

The tables which follow show what was found on the various strips and form most of the basis for such conclusions as are drawn.

Columns headed "Bearing Reprod. #" show the number of seedlings there would be per acre with every mil-acre occupied.

Columns headed "This Strip. #" show the number of seedlings per acre according to the actual distribution.

Composition percentages are the same for both columns.

Memo.

An increment borer was used on a number of trees to determine the age of the stands and to secure indications of the rate of growth.

From the standpoint of costs and results, it seems wholly impracticable to reduce the fire hazard on this area by any method of removal of the inflammable material, unless some market for the dead material opens up in the next few years. It is entirely improbable that such a market will appear because the material is suitable only for cordwood, mine material, charcoal, or some similar use, and it is not conveniently located with reference to existing means of transportation.

Should a fire occur on any of the areas examined, there are sufficient cone bearing lodgepole pine trees to practically insure a stand of lodgepole reproduction following the fire. In such event, the present stand of lodgepole timber, which has no sale value, would be lost, but the ground would probably not become unproductive because a new crop of lodgepole would immediately begin to lay on wood. Keeping these points in mind, it is apparent that this area is a low liability as compared to many others in the District.

Fire losses on the Missoula Forest for the period 1908 to 1919 inclusive, averaged three-fourths of one per cent of the net Forest area per annum, only half the average loss per annum for western Montana, or for the District, indicating that the hazard is relatively low, and the losses much less than in many other parts of the District. The protection organization has been greatly strengthened during the past four years, and for this area is now believed to be all that can be justified in comparison with other areas of greater hazard and higher values. This statement is made, taking into consideration the increased hazard due to insect depredations. Within these lodgepole areas examined, no traces of lightning stripes were found. This locality is not frequented during the dry season by great numbers of tourists or local campers, and there is no railroad or lumbering operation in the vicinity. Because of these conditions, fires are not of especially frequent occurrence.

Apparently, the dead trees begin to fall in considerable numbers through rotting off at the base about five years after they are killed. From about five years after killing the fall will probably be increasingly heavy for several years, and it will probably be twenty or more years after the trees are killed until practically all are down.

The control or prevention of destructive insect epidemics of this character in a stand of this kind is somewhat comparable to the control or prevention of fire in areas of low liability. In such cases in either fire or insect outbreaks, unlimited expenditures for suppression probably cannot be justified from any reasonable standpoint. If the outbreak can be taken vigorously in hand and controlled while it is very small, and cheaply controlled, action should, by all means, be undertaken. A similar policy has been in force in District One for several years with reference to fire suppression. (See page 101 of Instructions, Fire Protection, Northern District.) The case of fire differs from that of insects chiefly in that it often causes complete devastation and non-productiveness for many years while insects merely destroy a part of the existing stand and increase the fire risk in it.

Control action on an insect attack, if successful, may well be expected to prolong the life of the existing stand from ten to fifty years, perhaps even longer, depending on the age of the stand at the time it was attacked. It is an expedient remedy for an existing ill. True correction of the ill probably lies in an economic or utilization situation which will make possible the use of all timber as soon as it becomes mature, or as soon as an insect epidemic manifests itself, even though the timber lacks a little of maturity. The insect damage differs from that of fire in that the young growth and the soil are untouched by insects.

The most practical course for the immediate future, in lodgepole stands, appears to lie in prompt detection and reporting of incipient isolated epidemics, followed by vigorous control measures while the epidemics are still small in scope. Detection and reporting can be handled by the present Forest forces. Control will depend upon the availability of an ample emergency fund similar to the present Fire Fund. Congress appropriated \$25,000 for use in this way during 1924 fiscal year. The appropriation should be continued from year to year in a larger amount and made available for emergency use only.

CONCLUSIONS.

Approximately 72% of all lodgepole pine on the strips was killed by the work of the Mountain Pine Beetle. (*Dendroctonus monticolae*.)

There remains alive on the ground an uneven age stand of mixed species in which lodgepole pine at present predominates, forming 40% of the total number of trees larger than 6 inches D.B.H. and 38% of the young growth.

Memo.

The remaining green stand bears a much higher percentage of other species, (Douglas fir, larch, balsam, and spruce in the order named) than the original stand.

In the original stand, before the insect attack, including all three slopes, lodgepole made up 72% of the trees 6 inches D.B.H. and larger, yellow pine 2%, and other species 26%.

In the present stand, including all three slopes, lodgepole makes up 40% of the green trees 6 inches D.B.H. and larger, yellow pine a trace, and other species 60%.

In the 200+ year old stand on the northerly slope, lodgepole is probably about to disappear as an important component of the stand, since it now comprises only 9% of the green trees over 6 inches D.B.H. and only 2% of the young growth.

Many of the remaining green lodgepole trees are badly suppressed individuals of low or doubtful value as growing stock.

On approximately 20% of the lodgepole 140 years or less of age, the borings showed conclusive evidence of accelerated growth since the thinning by insects.

Most of the Douglas fir, spruce and larch in the stands 140 years of age and younger are sufficiently young and vigorous to make a good growth in the future. Some of the individuals show accelerated growth since the killing of the pine.

Many years, perhaps a full rotation, must pass before the stand again contains a volume of green timber equivalent to that which was on the ground just prior to the insect epidemic.

Of the seedlings 5 years of age and younger, a strikingly large percentage is Douglas fir.

The ground cover is still sufficiently complete to prevent erosion or soil deterioration.

The intensity of any fire that may occur and the amount of labor necessary for its control have probably been practically doubled by the insect infestation.

All of the lodgepole on these strips appears from very abundant scars to have survived at least one surface fire in the last 70 years.

During the next ten years, falling dead timber will greatly increase the cost of trail and telephone maintenance in the insect killed areas.

Memo.

Diameter rather than age seems to determine the susceptibility of the tree or the stand to insect attack.

Lodgepole in mixed stands appears to be attacked as freely as that in pure.

There is a negligible amount of active insect work in evidence in the remaining green lodgepole.

Control work in this locality is unnecessary because the epidemic has exhausted the host and passed on.

The stand is gradually passing over from lodgepole to Douglas fir as the predominating species, probably a common and orderly occurrence in the plant succession of the region.
